

Blade pitch control star device for a
rotorcraft rotor

This invention concerns the blade pitch control cyclic star devices 5 for the rotor of a rotorcraft or a rotary wing aircraft.

In the technical field of rotary wing aircraft, it is known that a cyclic star device is a specific device designed to transmit flight movements, set to a fixed index point with respect to the aircraft, toward the blades set on a rotating index, with the rotor shaft, about the axis of rotation of the latter.

More specifically, the invention refers to a cyclic star device for controlling the pitch of rotor blades, in particular a main helicopter rotor, which rotor is of the type shown schematically in figure 1, and for which each blade 2 is, on the one hand, driven in rotation about an axis of rotation Z-Z of a shaft 3 of rotor 1, or shaft S-S of rotor 1, by means of a hub 4 integral in rotation with shaft 3, and also integral in rotation about a longitudinal axis of pitch change A-A of blade 2, with at least one pitch lever 5 controlled by a corresponding pitch connecting rod 6.

As an example, in rotor 1 of figure 1, each pitch lever 5 protrudes on the leading edge side of corresponding blade 2 onto a sleeve 7 connecting said blade 2 to hub 4, sleeve 7, whose blade 2 is integral in rotation about the pitch axis A-A through its foot, linked with sleeve 7 by two pins 8, sleeve 7 itself being articulated on hub 4 in pitch, beating and drag, by an articulating mechanism rotating about three contributing axes perpendicular in two's as shown overall in figure 9.

More specifically, the invention refers to a pitch control type device including a set of cyclic stars 10, including two annular and coaxial stars enclosing the axis Z-Z of rotor 1, and mounted on a mechanism 2 guiding it in its axial translation (parallel to axis Z-Z of rotor 1 for controlling the collective pitch of blades 2), and in tilting (inclined in any direction about the axis Z-Z of rotor 1 to control the cyclic pitch of blades 2) of the stars with respect to axis Z-Z of rotor 1, and of which one is a

rotating star 12 connected, on the one hand to hub 4 and/or to shaft 3 by at least one device 13 driving the rotary star 12 in rotation with rotor 1 about axis Z-Z of the latter, and, on the other hand, with each blade 2 through the corresponding pitch connecting rod 6 with said rotating star 12 mounted to rotate via at least one
 5 bearing, with bearing housings generally comprising one or two ball races, on the other star which is a non-rotating star 14, itself connected on the one hand to aircraft structure 15 by at least one retaining device 16 immobilizing the non-rotating star 14 in its rotation about axis Z-Z of rotor 1, and on the other hand, to the pilot control devices 17, which solicit the non-rotating star 14 in such a way that the axial
 10 and/or tilting movements imposed on the non-rotating star 14 from the pilot controls are followed by rotating star 12 which transmits the pitch to be imparted to blade 2 of rotor 1 via the pitch connecting rods 6.

In general, the two stars 12 and 14 enclose shaft 3, and the pilot control devices 17 are three turbo control actuating devices (linear actuators) or similar
 15 actuating devices arranged between the non-rotating star 14 and the structure 15 of the rotorcraft, each articulated by swivels at their lower and upper ends respectively on said structure 15 and in a respective yoke of non-rotating star 14, whereas the pitch connecting rods 16 are understood to be between rotating star 12 and pitch levers 5 of rotor 1 blades 2 and are articulated by swivels at their upper and lower
 20 ends respectively on pitch lever 5 and in yokes set out on the perimeter of rotating star 12.

More often than not, mechanism 2 providing axial translation guidance and tilting guidance of cyclic stars 12 and 14 include a central swivel 18 centered on the axis Z-Z of rotor 1 on which one of the stars, in general the non-rotating star 14 and
 25 therefore also the rotating star 12 connected to star 14 by the bearing, are mounted to oscillate by at least one concave bearing surface plate 19 forming a spherical gap and working together with swivel 19, which is mounted to slide endwise (parallel to the axis Z-Z of rotor 1) about a cylindrical guide 20 coaxial with axis Z-Z and not rotating about this axis of rotor 1 and that is generally fixed with respect to the
 30 structure 15 of the rotorcraft. When the cyclic stars 12 and 14 enclose shaft 3,

which is more often than not the case, cylindrical guide 20 will be tubular, enclose shaft 3 and will be attached to a housing integral with rotorcraft structure 15 and enclose the basic link of shaft 3 to the main transmission box which drives shaft 3 and therefore rotor 1 in rotation about the axis Z-Z.

5 Also more often than not, the driving device (devices) 13 of rotating star 12, in rotation and/or the retaining devices 16, will prevent the rotation of the non-rotating star 14 and is or are one or several compasses respectively rotating or not rotating with two arms articulating scissors-wise and that are connected together by a pivot or hinge, enabling the two arms on each compass to spread apart or move
10 closer to one another allowing the movements of stars 12 and 14 in the direction of rotor 1 axis Z-Z because the upper and lower arms of each rotating compass 13 are also articulated respectively on shaft 3 or hub 4 of rotor 1 and on rotating star 12 and in such a way that the lower and upper arms of each non-rotating compass 16 are furthermore articulated on structure 15 of the rotorcraft and on the non-rotating
15 star 14.

 However, to remedy some of the drawbacks inherent in the use of rotating and/or non-rotating compasses, it has already been proposed to equip the cyclic star devices with driving and/or rotating devices having another structure, for instance a rotating or non-rotating pin, radially protruding toward the outside of the
20 respectively rotating or non-rotating star and engaged in a ramp, itself rotating with the rotor or, on the contrary, not rotating and connected to the rotorcraft structure as described respectively in patents US-6,280,141 and US-09/154,655 or yet again to use a mechanism guiding the translation and tipping of cyclic stars 12 and 14 which has a structure different from that including a central swivel 18 as described above
25 and which has two guide columns parallel to the rotor axis and symmetrical with one another either side of this axis in the same diametric plan passing through the rotor axis in a mechanism also including a universal joint link with an intermediate UJ ring mounted to slide endwise on the columns and articulated to swivel on these columns about a first diametrical axis of the ring, which is an axis remaining
30 perpendicular to axis Z-Z of rotor 1, whereas the universal joint ring is also

articulated to swivel on one of the two cyclic stars 12 and 14 about a second diametrical axis of the universal joint ring which is perpendicular to the first diametrical axis as proposed by DE-A-36 03 400 and DE-A-36 20 794, as well as in
5 movements of the cyclic stars 12 and 14 of the universal joint ring are guided by the two columns, whereas the tilting of the cyclic stars 12 and 14 in any direction about the axis Z-Z of rotor 1 are obtained by the swiveling of the cyclic stars 12 and 14 with respect to the universal joint ring about one of the two diametrical and perpendicular axes of said ring and by the swiveling of the ring on the columns
10 about either of these two perpendicular diametrical axes.

The guide columns may be of the rotating type (integral with rotor rotation) and therefore, in addition, the ring of the universal joint mounted in this case between the rotating columns on the one hand and on the other, the rotating star driven thus in rotation by the columns and the rings replacing the rotating compass
15 (compasses) (see US-09/154,655). But the guiding columns may also not rotate, i.e. be retained to prevent them from rotating about axis Z-Z of rotor 1 by a support attached to the rotorcraft structure, in which case the universal joint ring is also non-rotating and is mounted between, on the one hand, the non-rotating columns and on the other, the non-rotating star thus retained in rotation by the non-rotating columns
20 and the non-rotating universal joint ring replacing the non-rotating compass (or compasses) (see US-6,280, 141).

Note that the use of rotating or non-rotating guide columns does not prevent the simultaneous use of one or several compasses respectively non-rotating or rotating, because a device including both non-rotating columns and rotating
25 columns is not to be used in that it would not permit all the tilting movements required by the cyclic pitch controls and provided through the universal joint ring.

The cyclic star device in the technical embodiment now current, schematically and partially shown in a transversal half cross-section in figure 2 and in a plan drawing of figure 3, is actually a fixed column device (not shown) on which

the universal joint ring (also not shown) slides endwise and may tilt by two coaxial swiveling links about diametrical axis X-X, whereas the non-rotating star 14, in the internal radial position with respect to rotating star 12 and bearing 21 with two rows of balls interposed between two stars 12 and 14, supports two trunnions of universal joint 22 placed diametrically opposite each other and protruding radially toward the center of non-rotating star 14, and that are coaxial about a second diametrical axis Y-Y on which trunnions 22 pivot on the UJ ring.

Each of stars 12 and 14 is a solid monoblock and costly annular part because its engineering requires lengthy, tricky and accurate machining to obtain not only bearing surfaces cooperating with the rings of bearing 21, but also the three yokes 23 radially protruding toward the outside of lower axial part of non-rotating star 14 to take over from the pilot control devices such as 17 in figure 1 and the four yokes 24 (for a four-blade rotor) protruding radially toward the outside on rotating star 12 for taking up the lower ends of pitch connecting rods such as 6 in figure 1 and the two interconnecting fittings 25, which may also be arranged as a yoke to take up the lower end of the lower arms of the two rotating compasses (not shown but like 13 in figure 1) to drive the rotating star 12 in rotation.

The embodiment of figures 2 and 3 also reveals the following drawbacks in that bearing 21 would have to be manufactured to specific dimensions; bearing 21 is mounted tight against rotating star 12 of non-rotating star 14, or even both stars 12 and 14, leading to assembly difficulties in the workshop or in the event of the replacement of at least one of stars 12 and 14 at a user's, all the more so in that a corrosion fretting problem may arise at the interface level of bearing 21 assembly, also calling for the use of two flanges 26 and 27 attaching this bearing 21 to stars 14 and 12 and seal 28 and corresponding seal support 29, upper attaching flange 26 of lower ring 30 of bearing 21 also ensuring the pre-stressing of the same lower ring 30, split into two half-rings 30a and 30b, each for one of the two ball races and which are axially placed end to end and clamped against one another by the attaching of upper flange 26 to the upper end of non-rotating star 14 by means of an attaching star crown 32, which pre-stressing avoids any lifting away of the parts

forming bearing 21, and therefore any unwanted relative movement because of lower flange 27 retaining outer ring 31 of bearing 21 by means of a screw crown 33 attaching flange 27 under rotating star 12, screws 33 retaining simultaneously, above rotating star 12, support 29 of seal 28; the arrangement of all the cyclic stars 12 and 14 around the shaft, as in case 3 of figure 1, necessarily involves, in the event of a problem among users or on one of the arms arranged to form a yoke 23 or 24 on non-rotating star 14 and rotating star 12, removal of the main rotor assembly as shown in 1 of figure 1, i.e. of hub 4 and blades 2, which problem may be due to play in the assemblies, loss of torque load, corrosion phenomena, the appearance of cracks, blows received by these elements. The problems encountered on cyclic plates 12 and 14 are also due to the actual definition of each of the stars which consists of a large size rough part, therefore having a considerable weight and a high cost price.

The problem at the basis of the invention is to correct the drawbacks of the cyclic star devices of the prior technique in terms of complexity, numbers of parts, weight, cost of maintenance and cost of manufacturing.

The purpose of the invention is to propose a system of simple design cyclic stars using non-rotating and rotating modular link fittings that are simple to assemble and maintain among users, with a considerable gain in terms of weight and price.

For this purpose, the cyclic star device according to the invention for a rotor of the type shown above, itself of a type comprising two annular and coaxial stars enclosing axis Z-Z of the rotor and mounted on an endwise translation guide mechanism and also tilting for said stars with respect to rotor axis Z-Z, and of which one is a rotating star connected, on the one hand to the hub and/or the rotor shaft, by at least one device driving the rotating star in rotation with the rotor about its axis Z-Z, and on the other, with each blade by the corresponding pitch connecting rod, said rotating star being mounted to rotate by at least one bearing on the other star, which is a non-rotating star connected on the one hand to the structure of said

rotorcraft by at least one retaining device immobilizing said non-rotating star in rotation about said axis of rotor Z-Z and on the other, with pilot control devices soliciting the non-rotating star so that the axial and tilting translation movements imposed on the non-rotating star from the pilot controls are followed by the rotating
5 star which transmits the pitch to be imparted to the rotor blades through pitch connecting rods is characterized in that at least one of the two stars includes a modular assembly of interconnecting fittings to ensure links between said star and the pitch connecting rods and/or said driving device or with the pilot control devices and/or said retaining device at least, in that the interconnecting fittings of said
10 assembly are fixed rigidly and irremovably to an annular device of the corresponding star.

Naturally, the fittings for interconnection with one or several driving devices and/or with one or several retaining devices are only needed insofar as the rotation of the rotating star with the rotor and/or the retention of the non-rotating star against
15 any rotation is or are not ensured by the translation and tilting guide mechanism structure of the cyclic stars.

In an advantageous embodiment, the modular assembly of interconnecting fittings of said non-rotating star includes the first non-rotating interconnecting fittings that are identical to one another, in numbers equal to side pilot control devices, and
20 each of which connects said non-rotating star respectively to one of said pilot control devices, and/or said modular assembly of interconnecting fittings of said rotating star includes the first rotating interconnecting fittings, identical to one another, in numbers equal to the pitch connecting rods, and each of which connects said rotating star to respectively one of said pitch connecting rods. If the driving
25 devices of the rotating star or those retaining the non-rotating star fitted to the device are independent of the translation and tilting guide mechanism, the device would advantageously have the modular assembly of interconnecting fittings of said non-rotating star include at least a second non-rotating link fitting, in numbers equal to at least one said retaining device to connect said non-rotating star to at least one
30 retaining device and/or said modular assembly of interconnecting fittings to said

rotating device, include at least one second rotating interconnecting fitting in numbers equal to at least one driving device, to connect said rotating star to at least one said driving device.

Accordingly, by individually and separably attaching to the annular device of
5 the rotating star the first rotating link fittings and, as necessary, one or a second rotating link fitting, by this modular assembly of rotating link fittings, it is possible to reconstruct a rigid annular assembly corresponding essentially to a traditional rotating star, while benefiting from the advantage of being able to individually
10 disassemble and remove and rotating link fitting from this assembly and replace it, as the need arises, without action on the other rotating link fittings and without requiring the removal of the rotor.

The same applies to the first non-rotating link fittings and, where applicable, one or a second non-rotating link fitting which, when attached individually and separably to the annular device of the non-rotating star, reconstruct a rigid annular
15 assembly corresponding essentially to a conventional non-rotating star with the same advantages as outlined above for the disassembly and removal of each of the non-rotating fittings of the corresponding assembly.

These advantages are even more marked if the annular device of at least one of the stars, but preferably of each of them, consists respectively of the inner
20 and outer rings of the rotary assembly bearing of the rotating star on the non-rotating star.

However, to allow the adaptation of at least one modular set of interconnecting fittings to at least one of the two stars of the existing cyclic star assembly, while preserving the bearing and assembly mode, it may be
25 advantageous that, according to the invention, the annular device of at least one star is an intermediate ring force-fit with one of the inner and outer rings of said bearing, this arrangement being adopted for both rings if the need arises.

Further, that the annular device to which the interconnecting fittings of an assembly are secured removably are one of the rings of the bearing or an intermediate ring force-fit with one of the rings of the bearing with the attachment of the interconnecting fittings on the same assembly facilitated if these fittings are
5 attached to the annular device of the corresponding star via a collar integral with said annular device, and on which the interconnecting fittings are secured removably, preferably by bolting onto the corresponding collar, or by any other equivalent means of mechanical attachment.

Advantageously, each interconnecting fitting will have a plane form that is
10 more or less triangular, with one side forming a concave circle arc arranged as the attaching base with a perimeter part of said annular device corresponding to it, or with said corresponding collar, while the summit opposite said concave side is arranged to form a yoke or an end taking up the end swivel of a pitch connecting rod or a pilot control device or, where necessary, a drive device or a corresponding
15 retaining device.

If the interconnecting fittings are secured to collars, it is advantageous for the ring (inner or outer) of the bearing linked in rotation with the rotating star to be integral with an upper collar protruding more or less radially toward the outside of the bearing from the upper end of said ring linked with the rotating star and with
20 respect to axis (Z-Z) of the rotor, whereas the other bearing ring connected to the non-rotating star is integral with a lower collar protruding more or less radially toward the outside of the bearing from the lower end of said other ring (linked with the non-rotating star).

In this configuration, each pilot control device will preferably be linked by a
25 swivel-mounted link to respectively one of said non-rotating link fittings secured removably to said lower collar and/or each pitch connecting rod, preferably connected by a swivel-mounted link to respectively one of said first rotating link fittings secured removably to said upper collar.

Similarly, when at least one retaining device and/or at least one separate driving device of said translation and tilting guide mechanism is or are necessary, said at least one retaining device will be connected by a swivel-mounted link to a second non-rotating link fitting respectively secured removably to said lower collar and/or said at least one driving device connected by a swivel-mounted link to a second respective rotating link fitting secured removably to said upper collar.

The link fittings of at least one modular assembly can be constructed of aluminum alloy or composite material based on an aluminum or titanium metal matrix or from blanks or from forged or dye-punched blanks or plates.

When the bearing has two roller races, to ensure the pre-loading of the bearing in accordance with the embodiment of the technique, one of the bearing rings integral with one of the two non-rotating and rotating stars attached to said translation and tilting guide mechanism, will be subdivided into two half-rings placed endwise, end to end, each provided with one respectively of the two adjacent radial collars, tightened endwise against one another to ensure the pre-stressing of the bearing and through which said star is attached to said translation and tilting guide mechanism.

In a known manner, the translation and tilting guide mechanism may include a central swivel centered on rotor axis Z-Z on which the non-rotating star is mounted to oscillate by at least one block with a spherical cap bearing surface, said swivel mounted to slide parallel to the Z-Z axis of the rotor about a cylindrical guide coaxial with rotor axis Z-Z and not rotating about said rotor axis Z-Z, and preferably attached with respect to rotorcraft structure.

In this case, it is advantageous for said at least one plate to be connected removably, preferably by bolting, onto the two adjacent radial collars pre-stressing said internal bearing ring.

But as known, the translation and tilting guide mechanism may also include a universal joint link with a universal joint ring mounted to swivel, on the one hand,

about first axis diametrically corresponding to the ring of the UJ and perpendicular to the axis of the rotor, by two swiveling links coaxial with the two slides guided in axial translation, each respectively on one of the two guide columns parallel with the axis of the rotor and both symmetrical with respect to said axis in the same diametrical plane passing through the latter and, on the other hand, about a second diametrical axis perpendicular to the first diametrical axis, by two swiveling links with end trunnions placed diametrically opposite each other, connecting the universal joint ring to that of the two non-rotating and rotating stars, connected to said translation and tilting guide mechanism.

10 In this case, it is also advantageous for the two trunnions, for the assembly swiveling on the universal joint ring, supported by two adjacent radial collars provided for on the two internal half-rings of the bearing, to ensure axial pre-stressing.

Other advantages and characteristics in the invention will result from the description given below, considered non-limitative, of two examples of embodiments described with references to the attached figures, in which:

15 - figure 1 is a schematic representation of a four-blade rotor head equipped with cyclic stars according to the state of the technique, with an axial translation and tilting guide mechanism equipped with a central swivel and devices driving the rotating star and retaining the non-rotating star consisting respectively of rotating and non-rotating compasses, which device is described above,

20 - figures 2 and 3 are partial schematic views respectively of an axial section and plan view of a cyclic star device according to the technique, similar to that of figure 1 but with a translation and tilting guide mechanism of another known type, with a translated and articulated swiveling universal joint ring on two non-rotating columns,

25 - figure 4 is a partial schematic sectional and axial view of an initial embodiment of the cyclic star device according to the invention,

- figures 5 and 6 are views corresponding approximately and respectively to figures 2 and 3 of the technical embodiment for a second example of the cyclic star device according to the invention,

- figures 7 and 8 are schematic and perspective views of the side and
5 respectively top and bottom of a cyclic star assembly according to figures 5 and 6, and

- figure 9 is a schematic perspective view corresponding approximately to figure 7, with a representation of the universal joint ring and the slides guiding the device on two non-rotating columns.

10 Figure 4 is an axial half-section view of the central part of a cyclic star device 10' according to the invention with general architecture similar to that of the cyclic star device of figure 1 as concerns the translation and tilting guide mechanism 2', with a central swivel and the respective driving devices such as 13 and retaining devices such as 16, or respectively rotating and non-rotating compasses mounted
15 to rotor 1 according to figure 1 in such a way that the same numerical references as in figures 1 to 3 are provided, but assigned with a prime symbol and used to designate the elements corresponding to the example of figure 4.

In this figure 4, there is therefore a cylindrical tubular guide 20', coaxial with the rotor axis Z-Z and not rotating about it, because it is attached to the rotorcraft
20 structure, said guide 20' enclosing, without contact, rotor shaft 3 and a central swivel 18', amounted to slide parallel to the axis Z-Z about the guide 20'.

An annular plate 19' comprising two segments, having an internal radial bearing surface forming a concave spherical cap corresponding to the convex side of the outer side of swivel 18', mounted to oscillate on swivel 18', and the two
25 segments of plate 19' maintained to slide together against swivel 18' by an annular flange 34 with an internal radial collar 35 at the lower axial end and a collar 36 attached to the upper axial end, on which collar 36 is attached by screw crown 37. Radially toward the outside and in its central part, the annular flange has an outer collar 38 onto which are bolted, by an axial screw crown 39, the two internal radial

collars 50a and 50b, superimposed, and protruding, with respect to which the lower and upper respective ends of the inner upper half-ring 30' and the lower inner half ring 30'b are placed axially end to end to form an inner ring 30' of bearing 21' with two oblique contact ball races. Accordingly, the two inner collars 50a and 50b of the

5 inner half-rings 30'a and 30'b are used not only for pre-stressing bearing 31', but also for attaching inner ring 30' of the latter to the axial translation and tilting guide mechanism 2' comprising annular flange 34, plate 19' and swivel 18' sliding endwise on guide 20'.

The inner ring 30', in this way with flange 34, forms part of the non-rotating

10 star 14' attached to this guide mechanism 2'.

At its lower axial end, the inner lower half-ring 30'b is integral with a radial collar 40, protruding toward the outside of bearing 21', and on the perimeter of which are attached individually and separably, by axial screws 41, non-rotating link fittings of a modular assembly of said non-rotating fittings comprising three link

15 fittings 42, the outer radial end of which is arranged to form a yoke 43, and each of which is designed to ensure the linking of non-rotating star 14' with swivel 43a of the upper end of respectively one of the three pilot servocontrols 17 controlling translation and tilting of non-rotating star 14', said assembly of non-rotating link fittings also including another fitting (not shown), also bolted separately under the

20 outer perimeter of collar 40, and whose outer radial end is also arranged to form a yoke, for taking up an articulation, for instance a swivel, of the upper end of upper arm of a non-rotating compass linked by the lower end of its lower arm to the aircraft structure so as to retain non-rotating star 14' and prevent it from any rotation about the rotor Z-Z axis.

25 Similarly, the upper axial end of outer ring 31' of bearing 21' is integral with a radial collar 44 protruding toward the outside of bearing 21', and on the perimeter of which are bolted individually and separably by an axial crown of screws 45, the rotating link fittings of a modular assembly of such link fittings comprising four fittings such as 46, the outer radial end of each being arranged to form a yoke 47,

and each of which is intended for linking swivel 47a of lower pitch connecting rod end such as 6 in figure 1 on four-blade rotor, said rotating link fitting assembly also comprising two rotating fittings (not shown), also bolted under the perimeter of upper collar 44 and also arranged as a yoke to take up the articulations, for instance of the swivel type, on the lower ends of the lower arms of the two rotating compasses such as 13 in figure 1, to drive in rotation the rotating star 12' comprising outer ring 31' of bearing 21' with its collar 44 and the rotating link fittings of the corresponding assembly.

In the two link fitting assemblies described above, the three non-rotating fittings 42 are identical to one another, and the four rotating link fittings 46 are identical to one another, as are the two rotating fittings (not shown) linking the two rotating compasses such as 13. In addition, screws 45 simultaneously and rigidly attach to the collar 44 of inner ring 31', not only the rotating link fittings such as 46, but also an annular protection cover 48 which covers the upper ends of the two rings 30' and 31' of bearing 21', as well as the interface between them in such a way as to protect bearing 21' which includes waterproofing with grease. This bearing 21' will preferably be a stainless steel bearing with inside rings 30' and outside rings 31' of a stainless material, also forming collars 40 and 44.

All the rotating link fittings such as 46, and the non-rotating link fittings such as 42, may be manufactured of an aluminum alloy or as an alternative, of a composite material having an aluminum or titanium metal matrix, each from a simple blank of the forged or dye-punched type or, as an alternative, from a more common blank or even a standard plate shaped by high-speed machining.

In the second example of figures 5 to 9, we obtain (see figure 5) the bearing 21' with two ball races, the outer ring 31' of which is in a single part with upper collar 44, under the perimeter of which are bolted individually, by screws 45, all the rotating link fittings of the link fitting assembly equipping rotating star 12', of which the only annular device consists of the outer ring 31', with its upper collar 44. This assembly of link fittings includes fittings 46 of a first type, in equal numbers to the

rotor blades, and therefore to the pitch connecting rods such as 6 in figures 1; in this example, there are four fittings because the rotor is a four-blade rotor, while fittings 46 are identical to one another and each arranged, in its outer radial end, to form a yoke 47 designed to be connected by a swivel-mounted link to respectively one of the four pitch connecting rods. This set of rotating link fittings also includes at least one rotating fitting 49 of a second type designed to be connected, also by a swivel-mounted link, to a corresponding driving device such as a rotary compass 13 of figure 1. In this example, all the rotating fittings include two identical fittings 49, placed diametrically opposite one another (see figure 6), and each bolted by two screws 45 under collar 44 between two rotor link fittings 46 of the first type, because this second example of a cyclic star device has a rotary star 12' driven in rotation by two rotating compasses such as 13 in figure 1.

We also see that inner ring 30' of bearing 21', made of two inner half-rings 30'a and 30'b, mounted end to end axially and clamped one against the other by a crown of screws 39 screwed into the two inner radial collars 50a and 50b of the adjacent ends of half-rings 30'a and 30'b in order to pre-load bearing 21' on its lower half-ring 30'b to form a single piece with the outer lower radial collar 40, on the perimeter of which are bolted individually by screws 41, all the non-rotating link fittings of the modular link fitting assembly mounted on non-rotating star 14', the inner ring 30' of bearing 21 of which, with lower collar 40, forms the sole annular device. This system of non-rotating fittings includes three identical fittings 42 of the first type, the outer radial end of each being arranged to form a yoke 43 for connection, by a swivel-mounted link, to respectively one of the three pilot control devices such as 17 in figure 1, controlling the translation and tilting of non-rotating star 14'. The assembly of non-rotating link fittings shown in this example does not include a non-rotating fitting of a second type designed for connection by a swivel-mounted or swiveling link, to at least one device retaining non-rotating star 14' in rotation such as the non-rotating compass 16 of figure 1, because this second example includes a translation and tilting guide mechanism for non-rotating star 14' which is of the universal joint ring type, sliding and oscillating on two non-rotating

guide columns which simultaneously act as retaining devices for the non-rotating star 14', preventing it from rotating about the rotor axis Z-Z.

As shown in figure 6, the rotating link fittings 46 and 49 and the non-rotating link fittings 42, each having a more or less general triangular shape, with one side forming a concave circle arc, turned toward upper collar 44 or lower collar 40 corresponding to it, and forming a bolted attaching base thanks to screws 45 and 41 of the rotating link fittings 46 and 49 and non-rotating link fittings 42 respectively under collars 44 and 40 corresponding to them (see figure 5). On each of these fittings 46, 49 and 42, the apex opposite the concave circle arc side is arranged to form a yoke such as 47 and 43, with two parallel arms extending in planes that are more or less diametrical with respect to rotating star 12' and non-rotating star 14', whereas the yokes at the outer ends of interconnecting fittings 49 taking up the ends of rotating compasses have arms more or less perpendicular to the axis of the stars 12' and 14'.

In this example, there are also a protection cover 48 bolted by screws 45 onto upper collar 44 and covering the upper part of bearing 21'.

Concerning the translation and tilting guide mechanism of stars 12' and 14', this mechanism includes a universal joint link with a universal joint ring 51 (see figure 9), mounted to swivel on two trunnions 52 (see figure 6) that are coaxial and diametrically opposed with respect to the axis of stars 12' and 14', with a radial protrusion toward the inside of non-rotating star 14' on which trunnions 52 are supported by screws 39 on internal radial collars 50a and 50b of internal ring 30' of bearing 21'. The swiveling links via which the non-rotating star 14', and therefore the assembly of the two stars 12' and 14' turn about diametrical axis Y-Y of trunnions 52 on universal joint ring 51 are identified overall under 53 of figure 9. The universal joint ring 51 is also mounted to swivel about another diametrical axis X-X of this ring 51, which is perpendicular to the diametrical axis Y-Y of trunnions 52, by two coaxial swiveling links identified overall under 54 of figure 9, on two tubular slides 55, arranged to form bellows extending axially from the two sides of

the ring of universal joint 5.1, each of which is designed to be mounted and slide on respectively one of the two guide columns (not shown), parallel to the Z-Z' axis of the rotor and symmetrical with respect to one another and this axis, in the same diametrical plane passing through the latter, with the two columns attached to the rotorcraft structure.

A translation and tilting guide mechanism of this type, with a universal joint and a universal joint ring mounted to turn within the non-rotating star, on the one hand, and on the other on the two slides sliding parallel to the rotor axis on the fixed columns, described with respect to figures 5 and 6 of patent US-6, 280, 141, which gives more details on this subject. The translation and tilting guide mechanism partially represented in figure 9 of this request can be obtained as described in the aforementioned US patent.

With respect to the embodiment of the technical situation as shown in figures 2 and 3, it is clear that a cyclic star device according to the invention will produce a reduction in the number of parts: upper flange 28 and lower flange 27 attaching bearing 21 of figure 2 and support 29 of seal 28 are eliminated. The assembly of a device according to the invention is also simplified with respect to those of the technical situation, because the non-rotating link fittings, such as 42, and rotating link fittings such as 46 and 49 are attached individually by a mechanical assembly not requiring any special tooling and not representing any risk of damaging the bores of the rotating and non-rotating stars during assembly. On a helicopter equipped with a device according to the invention, the user has the possibility of changing a rotating or non-rotating link fitting without removing the blades or hub of the rotor, whereas the embodiments of the technical situation, all the cyclic stars must be repaired by an approved repairer after the removal of the rotor. With the device of this invention, the user can remove a damaged link fitting on an aircraft at his own level of maintenance, meaning a substantial reduction in time and cost. In terms of preventive or predictive maintenance, in conformity with the modern principles of removal of mechanical components according to their state, the fact of removing on the cyclic star device of the invention, modular link

fittings that are economical and easily replaced, contributes to a substantial reduction in the cost of maintenance.

In addition, a set of cyclic stars according to the state of the technique weighs approximately 55 kg for a helicopter weighing between 8 and 10 t, whereas
 5 a set of cyclic plates built according to this invention weighs approximately 45 kg for the same helicopter definition.

Simultaneously, a set of cyclic stars built according to this invention costs approximately ten times less than one produced according to the customary techniques for a helicopter of the range mentioned above.

10 Thanks to this invention, it is also possible to modify an existing cyclic star device. To do this, at the level of one and/or the other of the non-rotating and rotating stars, an intermediate ring can be added which allows, on the one hand, the force-fitting of the bearing ring linked with the corresponding star and on the other, includes a removable and individual attaching collar for the corresponding modular
 15 link fittings.

The advantage of a configuration like this is to allow adaptation of at least one set of modular fittings to an existing cyclic star device, while preserving the bearing and the assembly mode. This configuration can be adopted for either one of the inner and outer rings of the bearing.
